1 Introduction

Accessibility has been a large focus in tech and extended reality is no different. Ensuring that users with as wide a range of ability as possible to participate in the same digital landscape as any other. There has been emerging technology and research from understanding and creating better user interfaces (UI) to allow ease of use to creating and adapting new hardware and input devices to accommodate more users with physical disabilities. These accessibility choices to consider may range from physical design of a device with the interface to the placement of menus and icons to the very colors chosen to represent and convey information.

UI design has been intertwined with concepts such as color theory to optimize interface functionality for target users. This is due to not only to color choice having an effect on the usability of the interface itself, but also an effect on the user's mental cognition. This concept includes how color choices might effect how a person is able to find what they need within an interface and process how to use what they find (buttons, menus, icons). In a study on electronic note taking, it is mentioned that color choice can even effect the emotional status of a user, "The utilization of warm colors such as red or orange has the potential to evoke feelings of excitement or urgency, while cool colors like blue or green have the capacity to create a sense of calmness or trustworthiness." [1]

A gap in some technological accessibility research exists however, this research is often focused on usability and may push other factors such a educational value factors to the wayside. Recent studies have suggested that VR may play an important and beneficial role in the future of education, as stated here, "The results of the reviewed studies in their work show that learners who used an immersive HMD were more engaged, spent more time on the learning tasks, and acquired better cognitive, psychomotor, and affective skills. However, this study also identifies many factors that can be reinforcers or barriers to immersion and presence." [3] which then goes on to mention factors such as color and graphics quality having effect on learning. Further research into the fields of user accessibility and color theory may be needed to study the effects of UI color choice on user ability to learn new information and could assists in better interfaces from simple websites to complex VR programs.

This research study has been designed to address a specific case of color in UI and their effect on a user's ability to complete tasks based on how well they might learn them. This will specifically test how the different color icons and "wire" connections that the user makes while learning simple networking based lessons and completing tasks based on these short lessons. A small variety of preset and specifically chosen color palettes will be the variable that is tested for effect on user completion rate, error rate, and completion time over three short tests.

The following sections will cover the corresponding literature and research related to this study, the methodology designed for this study, the results, and analysis of the results.

2 Related Work

2.1 Color Theory and UI Design

The effects of color in user interface is not new and been slimming down the color choices made in interfaces of all kinds since early widespread use of computers and tech with interaction by lay persons. This is evident in the lack of high contrast and distracting design choices in most modern interfaces such as websites and cell phone applications. The switch from the anything-goes-approach of design in the late 1990s to calmer and more uniform choices was a natural progression in that early technology often focuses on function rather than form.

The current choice to make text simple to read and not high-contrast colors was simply due to ease of use which was catalyzed by early 2000s internet shopping. The easier it is for customer to understand a purchase and the process of the purchase, the more likely it is to complete a sell. This idea also works in simple use of technology and color choice can alter the intended effect of an interface, as stated in a conference paper by Guoying Wen, "The main goal of UI interface color design is to express color design more perfectly with the spirit and function of mobile Internet application, so as to arouse users' resonance, grasp users' psychology, and gain users' recognition and understanding." [5]

2.2 Educational Application of VR

VR in educational settings is a newer field of research but already is showing a possible benefit to learning. In a study from The University of Northhampton in the U.K., it is stated "Most students also noted that an equipment like the VR headset used in the experiment can genuinely improve concentration on the topic covered in class especially in a distracting environment (e.g., social media updates on smartphones or interruptions from other students)" [4] This study also mentions that the VR itself needs to be considered properly as "VR can potentially improve the understanding of a concept or visual information attributed to improved distraction-free engagement. However, students are less likely to recall or recognize specific details due to the additional cognitive load in VR." [4] which leads precedence to this papers research topic in color theory in educational environments using VR.

2.3 UI in VR

The study of UI in virtual environments has been a mainstay subject as it represents the largest aspect of the environment communicating information to the user. Whether it be through simple menus similar to traditional digital environments (desktops, mobile phones), or fully encompassing environments found in video games with immersive, dynamic UIs, the size, color, placement, shape, opacity, movement, or any other dynamic effect that an interface might have will eventually effect its overall usability. Though it is equally important to consider what not to do, especially in contained environments such as this paper's topic of color effect on VR educational environments. As mentioned in chapter 4 "Building UI in VR" in the book Google Daydream VR Cookbook: Building Games and Apps with Google Daydream, Unity, First Edition" by Same Keene "Even with the multitude of possibilities in VR, it turns out that the easiest way to consume basic information is the same way we do in the real world: on flat rectangular screens and often in text format." [2] which seems almosts a paradox with the amount of possibilities within extended reality spaces, but is important to note in design nonetheless.

2.4 Color and Learning

Color choice has an effect on many aspects of a persons cognitive function and learning is one of them. The color of a room a person is in, the hue of the lights in the room, the color of the font on a test they are taking, can have minute effects on a persons ability to learn and then take a test on the subject matter. Whether this be a drastic example such as unreadable font choice, or the more nuanced examples previously mentioned, color choices are worth considering. In a joint study on effects on education in color palette choices in PowerPoints slides by Tianjin Normal University (Tianjin, China) and University of North Texas (Denton, USA), it is suggested that groups of colors can have positive and negative effects. "The experiment results indicate that the PPT presentation in warm colors significantly enhanced learners' transfer of knowledge of Calligraphy, and its transfer scores are marginally positively correlated with positive emotions." [6]

3 Methodology

3.1 Baseline Data Collection

This study has been conducted using two human participants that served as the range that simulated users "performed" the tests in. The baseline level of users experienced with the educational topic of networking was created using the range of user ability with error rate and completion times considered. One experienced user with networking experience and certifications served as the high end of user range and one "typical" user with only home modem setup as experience as lower end of user ability range. This ensured that all simulated profile's performances fit within realistic data ranges set by human users to give most realistic results with simulated participants. Baseline test is the industry standard color palette (orange, green, purple, and red). All participants took part in same three test trial run using same interface placement, size, and font.

3.2 Simulated User Profiles

Simulated users based off the two human trials were used for this study. A group of 120 simulated participants in total were based off baseline data and subgroups of thirty were used for each color palette resulting in four groups. Python was used to create data randomly within bounds set by baseline human trial data, and also to add noise. These data factors were completion time, error total, and

3.3 Simulation Runs

Each simulated user has been "tested" using a custom python script to generate data points within the baseline scores set by human trials. Each of the four subgroups took the same three tests, with only difference being the color palette the user could choose from. Thirty users in each group were tested per color palette and the differences inside of and outside of groups was recorded. Group A had the standard industry colors (orange, green purple, red) that may be seen in professional networking environments, Group B had standard educational colors (red, green, blue, yellow), Group C had one bright neon, distracting palette and finally Group D had a similar color palette, but a muted, pastel version of the distracting palette. This allowed for realistic color palettes to be tested where no palette stood out too much as overly distracting or ineffective for intended participants (colorblind, etc.).

3.4 Tests

All participants took three standardized tests in which they display basic networking functions after a brief rundown on simple connections involving routers, switches, and common devices such as personal computers and mobile phones. These three tests increase in difficulty by having the participant make the correct wire connections to achieve a preset goal. The first test involves connecting a home style setup with router and devices. The second test involves the use of a switch in addition to the router and devices from previous test to simulate a

small office or small home network. The third test will build on second test and include second switch and more devices to simulate multi network office environment. The brief introductory phase will involve short description of router and switch and their roles in different networking environments. The only difference between tests were the different color palettes used for the simulated wire connections based on participant grouping. These tests are designed to allow for a basic introduction to simple and common networking setups as not to overwhelm the participants with complex networking information. This was important to keep the focus of the study on the effects of how color affects participant performance in these tests.

3.5 Statistical Analysis

Standard ANOVA testing was done on the results to assess levels of variance found within and between groups. Groups of thirty were used to result in medium effect size with power of 80%.

4 Results

4.1 Task Completion Rate

4.2 Error Rate

4.3 Task Success Rate

4.4 Color Palette Comparison

5 Discussion

5.1 interpret results

5.2 compare to prior research?

5.3 Limitations of Study

There were several limitations imposed on the study by natural bounds. The first and most important of note is that user data was simulated. Baseline data was established using human participants to create a realistic range for simulated data to fall within and despite this, data that is fully simulated cannot capture all variables and unmeasured effects of human computer interaction (HCI) within a VR environment.

The datasets were formulated as being two separate concepts, the first being a set that represents performance on the network test itself and data points related such as completion time and error rate. The second being HCI focused data points such as time to move controller from place to place and time spent gazing at specific places in VR environment. Simulated data in this sense will not be able to be used to establish further data points or theories.

The human data sets used as ranges for simulated data are significantly limited as well with a sample size of ($n=2$) presenting another level of generalization in the end results. This limitation has been acknowledged to show lack of representation of the diversity found in ability, prior knowledge, and learning speed found in human populations.

Another limitation is placed by the focus of the study being on color in educational environment specifically within in simple IT networking. Results from a study that may be set similarly or completely the same but with non-simulated data may find that results are very specific and may not be representative of performances in other educational contexts, especially those where color make take a different role than like in networking cable colors.

The limitations on this study suggest that current data analysis and methodology should only be viewed as exploratory and as a study that sets up a framework for further research into color usage in educational VR environments.

5.4 Applications

Although the previously mentioned limitations exist, this studies structure and methodology may be practical in several applications, specifically within VR educational environments but potentially with some of the abstract setup as well.

The mix of simulated data based on human data used as ranges provide a template for smaller and resource limited teams to develop preliminary designs and prototype before committing to larger studies. This is a necessary trade of accessibility to create studies and fully valid data.

For the specific VR program developed in this study, it may possibly used a template for further color related studies as the program was built with modification of elements such as color palette and test requirements being central.

6 Conclusion

6.1 Summary

This study was created to research the effects of color choice in UI and how those color choices can change performance within educational testing environments. By testing four distinct color schemes in the form of industry standard, educational standard, colorblind friendly, and a distracting palette, this was attempted to find any potential influence on user performance through input tracking.

The methodology was limited in terms of baseline data by way of small human sample size and then simulated data based off of those human created data values. Additionally, the very basis of the study being centered on an aspect of vision, simulated data may not represent a wide range of real human ability within a VR environment. Even in acknowledging the limits of the study by way of simulated data, the basis of the study establishes some groundwork in study of color theory and effects of use in UI in VR environments.

6.2 Recommendations for Future Studies

Either removing simulated data entirely, or increasing the human participants amount to create a more accurate baseline of data would improve data output validity significantly. The concept of the study being on effects of color choice in UI inherently relies on visual ability and this would be fully amended by using human participants instead. This would be the single largest change from this first iteration, to produce intended data output.

Increasing data tracking data-points would also expand the potential for statical significance to show in how performance is effected when different color palettes are used. Expanding on the human-computer interface related data points specifically would enhance the study value within an extended reality educational environment.

The modularity of the testing setup allows for further color study in other fields as well. By simply changing the test prompts and icons, this study can be fitted to many other educational schemes such as chemistry, computer science, etc.

Lastly, additional multi modal features could be implemented and tracked such as more haptic feedback, audio cues, and gaze based functionality. This would allow for study into optimal modal combinations within color based studies as well.
